Abstract
The oral pyogenic granuloma is a commonly occurring tumor like reactive lesion that occurs as a response to different stimuli such as hormonal imbalances, low grade chronic irritation, trauma or certain type of drugs and oral contraceptives. It is frequently seen in the gingiva, and also lips, tongue and buccal mucosa are the other commonest sites. The present case reports a localized inflammatory hyperplasia of the maxillary gingiva of a 20-year-old male patient which was interfering with normal eating and brushing.

Keywords: Pyogenic granuloma, Diode laser, Gingival enlargement.

Introduction
Pyogenic granuloma (PG) is a well-known benign inflammatory hyperplastic growth seen inside the oral cavity as a tissue reaction to irritation, trauma, or hormonal imbalances. The term “pyogenic granuloma” is a misnomer as it is a non-neoplastic lesion of vascular origin, also it does not contain pus nor it is granulomatous. It is considered as capillary haemangioma. It was first described by Hullihan in 1844.¹ Other names for the pyogenic granuloma are granulation tissue-type haemangioma, granuloma gravidarum, lobular capillary haemangioma, pregnancy tumour, eruptive haemangioma.²

It is presented as an elevated sessile or pedunculated growth, surfaced with red hemorrhagic and erythematous papules covered by a fibrinous membrane that usually shows ulcerations. Based on the vascularity of the lesion, the color varies from purple pink to red. Clinically, the lesion rarely exhibits rapid growth, is symptomless, and does not cause pain. The radiographic findings are typically absent, but in long standing gingival Pyogenic granuloma, localized alveolar bone resorption can be seen.³ Marginal gingiva is the most common intraoral site to be affected by pyogenic granuloma but lesions have been reported on palate, buccal mucosa, tongue, and lips. The skin of face, neck, upper and lower extremities, and mucous membrane of nose and eyelids are also commonly involved extraoral sites.²

The Conventional Excisional therapy is the treatment of choice for pyogenic granuloma, but some alternative approaches such as cryosurgery, electrosurgery, laser therapy, flash lamp pulsed dye laser, injection of corticosteroid or ethanol, sclerotherapy have been reported to be effective. The definitive treatment involves excision of the lesion along with histopathological evaluation to confirm the diagnosis. Careful monitoring is necessary during the excision of PG because of its vascular nature leading to profuse bleeding and it should be completely removed otherwise recurrence chance is more. The biggest disadvantage of conventional surgical excision is difficulty of controlling bleeding during the surgical procedure.⁴⁻⁵

Since the introduction of laser in dentistry, different wavelengths have been used for oral soft tissue dental procedures. Various laser devices have been successfully used to treat PG, such as neodymium-doped yttrium aluminium garnet (Nd:YAG), carbon dioxide laser, erbium-doped yttrium aluminium garnet (Er:YAG), and the diode laser. The dental laser is able to provide clean incision of tissues, immediate coagulation, and minimal postoperative pain, and edema. Minimum surgical expertise is required with laser therapy as compared to conventional surgical excision.⁶⁻⁷

The diode laser acts as a semiconductor device consisting of several active medium like aluminum, gallium, arsenide, and occasionally indium. The coherent radiation is produced by the device in the visible or infrared spectrum with wavelengths ranging from 810 nm to 980 nm. Thus, the pigmented tissues like melanin and hemoglobin tend to absorb all wavelengths properly. However, they are poorly absorbed by calcified tissue such as hydroxyapatite and water present in the enamel.⁵ Several studies have reported success using diode lasers in surgical procedures performed on soft tissues. Diode laser therapy is simple, safe, non-invasive and completely effective for oral soft tissues. High precision, negligible blood loss and better patient compliance are the advantages associated with it. The diode laser ensures various procedures like Cuts, vaporization, curettage, coagulation, and hemostasis.⁸

This case report presents a case of a peculiar Oral Pyogenic Granuloma in a young adult patient excised successfully with minimal postoperative complications and also highlights the use and advantages of diode laser in the surgical excision of oral pyogenic granuloma.

Case Report
A 20-year-old male patient reported to the outpatient Department of Periodontics with the chief complaint of painless overgrowth of gum related to upper left back teeth region in the oral cavity. The growth was associated with frequent bleeding and interfered with normal eating and brushing. He first noticed the growth 2 months back when it was very small and gradually increased to reach the current
size. (Fig. 1) The medical and family history were not significant. No extraoral swelling was found on extraoral examination. On intraoral examination, during inspection, an elongated oval-shaped, pedunculated mass-like growth seen in relation to the buccal aspect of gingiva with respect to 25, 26 teeth region, measuring approximately 2.5 × 3 cm. The Colour of the growth was dark red and surface was smooth. The growth covered approximately whole of the interdental region of the teeth. This erythematous and distinct growth was originating from the marginal gingiva and interdental gingiva in relation to 25 and 26. On palpation, the mass was well defined, smooth, and soft to firm in consistency and non-tender. The lesion was bleeding on probing. Periodontal examination revealed 5mm of pocket probing depth in relation to the interdental area between 25 and 26. (Fig. 2) Radiographic examination showed the mild alveolar bone loss in the involved region and hematological examination revealed normal blood values.

The treatment plan included oral prophylaxis and excisional biopsy of the growth with diode Laser. Written informed consent was obtained from the patient prior to the laser excision of the lesion and all necessary precautions were taken throughout the procedure.

The surgical area was anesthetized using local anesthetic agents (2% lidocaine with 1/100,000 epinephrine), the lesion was treated by Soft-tissue Diode Laser (Biolase Epic 10 Diode laser 940nm, USA) with continuous wave, in contact mode with a power output of 2 watt. A 0.4-mm diameter disposable laser fiber optic tip was initiated. (Fig. 3) The tip was moved around the base of the lesion with a circular motion at a slight angle of 5 to 10 degrees. The base of the lesion was cut precisely. As massive hemorrhage from the surgery area was seen, therefore, the laser fiber tip was moved in a sweeping motion on the surgical site in order to achieve coagulation and after 30 seconds the bleeding was stopped. The area was left for healing with secondary intention. (Fig. 4) The procedure took 3-4 minutes to complete. The mass was excised completely as one piece, and immersed in 10% formalin solution and sent for histopathological examination. (Fig. 5) The patient was discharged with well written prescription and all the necessary post-operative instructions for maintenance of good oral hygiene with 0.12% chlorhexidine mouth rinse for 10 days, and scheduled for routine scaling and curettage. He was recalled for followed up to evaluate the healing process. The use of diode laser enabled an optimum combination of clean cutting of the tissue and hemostasis. The patient was extremely comfortable, reported no post-operative complications, and complete healing was observed within 7 days after surgery. (Fig. 6)
Histopathological Examination
The excised mass was sent for histopathologic evaluation. The H&E stained section of tissue showed para keratinized stratified squamous epithelium with thin elongated and irregular reteridges overlying fibrovascular connective tissue stroma. The epithelium showed prominent nucleoli and prominent intercellular junctions. The underlying fibrovascular connective tissue stroma showed thick and thin collagen fiber bundles interspersed with plump fibroblasts. Numerous blood vessels of varying caliber were seen lined by endothelial cells. Areas of hemorrhage and dystrophic calcifications were also evident. Diffuse mixed inflammatory cell infiltrate was seen chiefly composed of neutrophils, plasma cells and lymphocytes. The above histopathologic features were suggestive of pyogenic granuloma. (Fig. 7-9)

Discussion
The oral pyogenic granuloma is a most common tumor like reactive lesion having etiological factors such as low grade chronic irritation, hormonal imbalances, trauma or certain type of drugs and oral contraceptives. It occurs at any age but most frequently affecting young adults and women. The anterior maxillary gingiva is involved more frequently than the mandibular gingiva; the facial gingiva is involved more than the lingual gingiva. Poor oral hygiene and chronic oral irritation are most frequent risk factors. Early lesions bleed easily due to extreme vascularity and have a rapid growth pattern.10

Histopathologically, oral pyogenic granuloma is considered into lobular capillary hemangioma (LCH) because of its inflammatory nature and presence of multitudinal blood vessels. The histologic appearance of pyogenic granuloma shows exuberant granulation tissue which is covered by hyperplastic epithelium that may be ulcerated at times. It is characterized by the presence of numerous endothelium-lined vascular spaces and proliferation of fibroblasts and budding endothelial cells. Presence of mixed inflammatory cell infiltration can also be observed. The differential diagnosis of pyogenic granuloma includes peripheral giant cell granuloma, pregnancy tumor, peripheral ossifying fibroma, bacillary angiomatosis, metastatic cancer, kaposi’s sarcoma, and non-hodgkin’s lymphoma, angiosarcoma, hyperplastic gingival inflammation and hemangioma.11

Conservative surgical excision of a pyogenic granuloma is the treatment of choice. Depending on the extent and size of the lesion management of pyogenic granuloma varies. The excised tissue should be submitted for histopathologic examination to make a proper diagnosis. Bleeding, suturing, and postoperative discomfort are the major drawbacks of surgical intervention. Re-excision is necessary in case if the lesion recurs. Other less invasive treatment modalities have been attempted in the past with limited benefits, such as: cryosurgery, cauterization with silver nitrate, sclerotherapy.12

Among the various treatment modalities, the advantages of laser application are relatively bloodless surgery, better visualization of the site and a sutureless procedure with minimal postoperative pain. Additionally, the laser instantly disinfects the surgical wound with...
The laser therapy is a successful treatment option for this kind of lesion with no recurrence.
